ABSTRACT

A series of V/ZrCe_x catalyst synthesized by a co-precipitation method was employed to investigate the simultaneous removal of NO and elemental mercury (Hg⁰) in simulated flue gas. The catalysts were characterized using BET, SEM, XRD, H₂-TPR, XPS, and FT-IR. V/ZrCe_{0.6} with CeO₂/ZrO₂ molar ratio of 0.6 showed excellent SCR activity (87.3%) and high Hg⁰ oxidation efficiency (77.6%) in SCR atmosphere (NH₃/NO = 1). The results indicated that the Hg⁰ had little impact on NO conversion, while the coexistence of NO and O₂ would be beneficial for the Hg⁰ oxidation. Hg⁰ oxidation was inhibited in SCR atmosphere owing to the presence of NH₃. The characterization results demonstrated that the superior performance of V/ZrCe_{0.6} catalyst might be attributed to lower crystallinity, better texture properties, strong redox ability and high reactive nitrate together with NH₃ species. The redox equilibrium (Ce³⁺ + V⁵⁺ ⇌ Ce⁴⁺ + V⁴⁺) contributed to the NO conversion and Hg⁰ oxidation. The bidentate sulfates formed by adsorbed SO₂ could provide new acid sites for NH₃ adsorption and increase the amount of NH₄⁺, which reduced the poisoning effect of SO₂ and H₂O. Based on the experimental results, a mechanism for the simultaneous removal of NO and Hg⁰ was proposed for the V/ZrCe_{0.6} catalysts: 2NH₃/NH₄⁺(ad) + NO₂(ad) + NO(g) → 2N₂ + 3H₂O + /2H⁺, Hg(ad) + O₂ → HgO(ad).

1. Introduction

Coal combustion is a major anthropogenic emissions source of NO_x and elemental mercury (Hg⁰), which are considered as significant atmospheric contaminants and have attracted broad attention in recent years [1–3]. NO_x could lead to worsening local air quality, regional acid rain pollution and photochemical smog [4,5]. Mercury can be a threat to both human health and the environment due to the extreme toxicity, persistence, and the bioaccumulation [6,7]. Consequently, various environmental laws and regulations for the prevention and control of NO_x and Hg⁰ pollutions have been enacted [8,9].

By far, the most successful and mature processes for controlling NO_x and Hg⁰ are selective catalytic reduction (SCR) [10,11] and activated carbon injection (ACI) systems [12,13], respectively. However, the separate NO_x and Hg⁰ control technology results in the low efficiency of apparatus, large equipment investment, and

high operation cost [5]. As a result, the cost-effective methods that can remove NO_x and Hg⁰ simultaneously need to be investigated. Recent studies indicated that catalysts employed in the selective catalytic reduction (SCR) of nitrogen oxides can promote the oxidation of Hg⁰ [14–16]. Hence, SCR catalysts are one of the promising materials for simultaneous removal of NO and Hg⁰, in which the key is to reduce NO by NH₃ and oxidize Hg⁰ to the soluble Hg²⁺. Although some metal oxides catalysts, such as Mn-Ce/Ti-PILCs, CeO₂-MoO₃, CeO₂-MnO_x/TiO₂, and V₂O₅-CeO₂/TiO₂, have been investigated for simultaneous removal of NO and Hg⁰ [1,17–19], a systematic investigation on the influence mechanism of SO₂ as well as a connection between Hg⁰ oxidation and NO conversion have rarely been reported.

Over the past few years, supported vanadium catalysts have attracted considerable attention due to their excellent advantages including high activity, selectivity and resistance to sulfur dioxide. In general, the nature of support was found to play a huge influence on the physicochemical and catalytic properties of the supported vanadium oxide catalysts [20]. Accordingly, scholars have tried a variety of vanadium based catalyst with different supports, such as alumina, zirconia and titania. As a typically support of SCR catalysts,

TiO_2 may not be ideal owing to its low specific surface area and poor thermal stability [21]. Due to unique physicochemical properties, ZrO_2 is widely used for catalysts, particularly employed as catalyst carrier in the SCR of NO_x by NH_3 [22]. CeO_2 , can be utilized as catalyst support, promoter or even active species, possesses considerable oxygen storage capacity owing to the redox cycling between Ce^{3+} and Ce^{4+} , which has been already widely used as a crucial component in three-way catalysts (TWCs) [23]. In addition, there is a synergistic interaction between V_2O_5 (V) and CeO_2 (Ce), which could result in the high SCR performance and enhance the activity of Hg^0 oxidation [16,24]. However, pure CeO_2 showed poor stability and was susceptible sintering at high temperatures [25]. The insertion of ZrO_2 (Zr) into CeO_2 can improve the thermo-stability, mobility of lattice oxygen and the density of oxygen vacancies, because part of Ce^{4+} in CeO_2 is replaced by Zr^{4+} to form the cubic fluorite structure of CeZr mixed oxides. Therefore, there is reason to believe that CeZr supports may have good performance in SCR catalytic systems. Recently, CeZr-based catalysts were studied for SCR of NO with NH_3 [22,25,26]. For example, the $\text{V}_2\text{O}_5/\text{CeO}_2-\text{ZrO}_2$ (V/CeZr) catalysts showed high activity and selectivity for reduction of NO with NH_3 [22]. However, $\text{V}_2\text{O}_5/\text{ZrO}_2-\text{CeO}_2$ (V/ZrCe) has seldom been reported for simultaneous removal of NO and Hg^0 .

The aim of this study was to understand the catalytic mechanism for simultaneous removal of Hg^0 and NO over $\text{V}_2\text{O}_5/\text{ZrO}_2-\text{CeO}_2$ and to clarify the effect mechanism of SO_2 on the reaction. A connection between Hg^0 oxidation and NO conversion was also systematically investigated. The physicochemical properties of the catalysts were systematically examined using some characterization methods including scanning electron microscopy (SEM), X-ray diffraction (XRD), Brunauer–Emmett–Teller (BET), temperature-programmed reduction of H_2 (H_2 -TPR), X-ray Photoelectron Spectroscopy (XPS), and Fourier transform infrared spectroscopy (FT-IR).

2. Experimental

2.1. Synthesis of catalyst

$\text{ZrO}_2-\text{CeO}_2$ binary oxide supports were synthesized using a co-precipitation method. A certain amount of $\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ and $\text{ZrO}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ were used as precursors and dissolved in de-ionized water; the solutions were subsequently heated at 80 °C and stirred 30 min. After the solution cooled to room temperature, an aqueous solution of ammonia was added drop-wisely with vigorous stirring until the pH rose to 10. The resulting precipitates were stirred for 3 h and aged for 1 h at room temperature; after being filtered, the solid product was dried at 80 °C overnight, and then it was calcined at 500 °C for 4 h in air. The obtained $\text{ZrO}_2-\text{CeO}_2$ supports are denoted as ZrCe_x , where x represents the molar ratio of $\text{CeO}_2/\text{ZrO}_2$ (x = 0.2, 0.4, 0.6, 0.8, 1.0). The support materials of CeO_2 (Ce) and ZrO_2 (Zr) were prepared with the same process.

A series of V/Ce, V/Zr and V/ZrCe_x catalysts were prepared by impregnating the support powders of Ce, Zr and ZrCe_x with ammonium metavanadate solution for 12 h, and the molar ratio of V/Ce, V/Zr and V/ZrCe_x was all 0.03. Then the samples were dried at 105 °C overnight and calcined at 500 °C for 3 h. Finally, the samples were crushed and sieved to 100–120 mesh.

2.2. Characterization

The catalyst microstructure was analyzed were determined by scanning electron microscopy (SEM) (Hitachi S-4800, Hitachi Limited, Japan). The separated areas for each catalyst were magnified to 100,000×.

The Brunauer–Emmett–Teller (BET) surface area, pore volume and average pore diameter of catalysts were obtained from N₂

adsorption isotherm using a Micromeritics Tristar II 3020 analyzer (Micromeritics Instrument Crop, USA). The specific surface area was calculated the N₂ desorption plots of the catalysts.

The crystalline phases of the catalysts were determined by X-ray diffractometer (Rigaku rotaflex D/Max-C, Japan) in the scattering angles (2θ) rang of 10–80° with Cu-Kα radiation (λ = 1.5406 Å).

X-ray Photoelectron Spectroscopy (XPS) data were obtained on a K-Alpha 1063 system (Thermo Fisher Scientific, UK) with an Al Ka X-ray source. The binding energy (BE) was calibrated by C 1s at 284.6 eV.

The Fourier Transform Infrared Spectroscopy (FT-IR) was recorded on a FTIR-8400S IRprestige-21 (SHIMADZU, Japan) apparatus. The IR spectra were recorded with 20 scans at a spectral resolution of 2 cm⁻¹. Prior to each measurement, the samples were treated at 250 °C in pure N₂ for 30 min to remove any adsorbed species, and cooled to room temperature. The total gas flow was 500 mL/min. The adsorption of NH₃ was carried out at room temperature for 1 h using a gaseous feed of 700 ppm NH₃/N₂. Subsequently, the FT-IR experiments were conducted immediately. A similar procedure was applied to study the NO + O₂ (700 ppm NO, 6% O₂/N₂), SO₂ + O₂ (300 ppm SO₂, 6% O₂/N₂), and SO₂ + H₂O + O₂ (300 ppm SO₂, 8 vol.% H₂O, 6% O₂/N₂) co-adsorption by treating the samples, respectively.

Temperature-programmed reduction of H₂ (H₂-TPR) was performed on a AutoChem 2920 automated chemisorption analyzer (Micromeritics Instrument Crop, USA) with approximately 1 g catalyst to analyze the redox properties of the catalysts. In order to eliminate the adsorbed volatile impurity, the catalysts were pretreated in pure N₂ at 300 °C for 30 min and then cooled to room temperature, performed in a flow of H₂ (5 vol.%) in Ar (40 mL/min) from 50 to 750 °C with a heating rate of 10 °C/min.

The temperature programmed desorption of ammonia (NH₃-TPD) was carried out using TP-5080 automatic chemical adsorption instrument (Tianjin Xian Quan, China). Prior to the experiment, the 200 mg sample was pretreated at 500 °C with a gas flow of He (30 mL/min) for 30 min. Then the samples were cooled down to 100 °C and exposed to NH₃ until saturation was reached, followed by flushing with pure He at the same temperature to avoid physisorption of NH₃. Afterwards, the NH₃-saturated samples were heated up to 600 °C at a heating rate of 10 °C/min in He.

2.3. Catalytic performance test

A schematic diagram of the experimental setup is shown in Fig. 1. The catalytic activity measurement for the removal of NO and Hg^0 was carried out at atmospheric pressure in a fixed bed continuous flow quartz reactor with i.d. 10 mm 0.25 g catalyst was placed in the reactor. The composition of simulated flue gas (SFG) including 700 ppm NO, 700 ppm NH₃, 6% O₂, 300 ppm SO₂ (when used), and N₂ (as balance) were precisely controlled by mass flow controllers (MFC). SCR atmosphere was defined as 6% O₂, 700 ppm of NO, and 280–700 ppm of NH₃ balanced in N₂. 70.0 μg/m³ Hg^0 was generated by a Hg^0 permeation tube (VICI Metronics, USA). In order to avoid Hg^0 and water vapor condensation, all teflon tubes that Hg^0 and water vapor passed through were wrapped with a temperature-controlled heating tape and heated up to 120 °C. 8 vol.% H₂O (when used) was exactly controlled by peristaltic pump and injected into the teflon tube. 100 mL/min pure N₂ took along the water vapor to mix with the SFG. The gas was introduced into the reactor with the inlet flow rate at 500 mL/min, corresponding to a gas hourly space velocity (GHSV) of 100,000 h⁻¹. The steady-state tests were conducted from 100 to 400 °C. The NO and Hg^0 concentrations at the inlet ($\text{NO}_{\text{in}}/\text{Hg}^0_{\text{in}}$) and outlet ($\text{NO}_{\text{out}}/\text{Hg}^0_{\text{out}}$) of the reactor were measured respectively by a flue gas analyzer (MGA5, Germany) and an online RA-915 M mercury analyzer (LUMEX Ltd, Russia). Before proceeding to the mercury analyzer, acid gases and

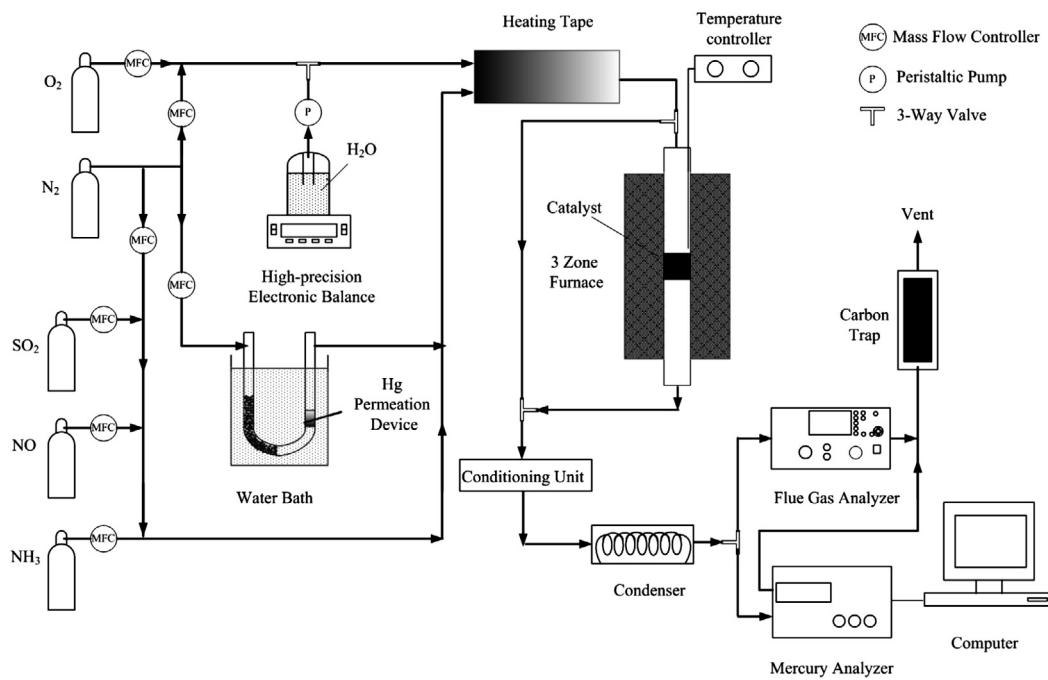

Fig. 1. Schematic diagram of the experimental setup.

NH_3 were removed by the conditioning unit which converged to a 10% NaOH solution. At the same time, water vapor was removed by the condenser. An adsorption experiment conducted at room temperature, and 0.25 g of V/ZrCe_x catalysts were saturated with $70.0 \mu\text{g}/\text{m}^3 \text{Hg}^0$ under N_2 atmosphere in less than 10 min, indicating that the Hg^0 physical adsorption capacity of the V/ZrCe_x catalyst was negligible [27–29]. The decrease of Hg^0 concentration during an experiment was attributed to Hg^0 oxidation. Accordingly, the Hg^0 oxidation and NO conversion were respectively defined in Eqs. (1) and (2):

$$\eta_{\text{Hg}}(\%) = \frac{\text{Hg}_{\text{in}}^0 - \text{Hg}_{\text{out}}^0}{\text{Hg}_{\text{in}}^0} \times 100\% \quad (1)$$

$$\eta_{\text{NO}}(\%) = \frac{\text{NO}_{\text{in}} - \text{NO}_{\text{out}}}{\text{NO}_{\text{in}}} \times 100\% \quad (2)$$

3. Results and discussion

3.1. Catalytic performance

3.1.1. Catalytic activity of V/ZrCe_x catalysts

The simultaneous removal performances of NO and Hg^0 in SCR atmosphere ($\text{NH}_3/\text{NO} = 1$) were investigated at the temperature of 100–400 °C and the results are shown in Fig. 2. It was clear that the catalytic activity was influenced by the molar ratios of Ce/Zr. For the V/ZrCe_x catalysts with different Ce/Zr ratios, the Hg^0 oxidation and NO conversions first increased and then decreased again as the Ce/Zr ratio increased. The $\text{V}/\text{ZrCe}_{0.6}$ catalyst exhibited the best Hg^0 oxidation and NO conversion. At 250 °C, Hg^0 oxidation efficiency and NO conversion was 77.6% and 87.3%, respectively. The possible reason was that the $\text{V}/\text{ZrCe}_{0.6}$ exhibited the largest BET surface area (as shown in Table 1) during the Ce/Zr ratios increasing from 0.2 to 1.0, which might affect the Hg^0 oxidation efficiency and NO conversions of V/ZrCe . Compared with the V/Zr catalysts, the addition of Ce widened the operating temperature window for the reaction as well as considerably improved catalytic performance (250–300 °C). It can be deduced that Ce added to V/Zr enhanced the

Table 1
BET surface and pore parameters of the different catalysts.

Catalysts	BET surface area (m^2/g)	Pore volume (cm^3/g)	Average pore diameter (nm)
V/Zr	41.6	0.0745	7.16
V/Ce	41.3	0.0976	9.45
$\text{V}/\text{ZrCe}_{0.2}$	47.4	0.0445	3.75
$\text{V}/\text{ZrCe}_{0.4}$	48.7	0.0458	3.77
$\text{V}/\text{ZrCe}_{0.6}$	58.5	0.0708	4.84
$\text{V}/\text{ZrCe}_{0.8}$	56.7	0.0743	5.24
$\text{V}/\text{ZrCe}_{1.0}$	51.5	0.0728	5.65

catalytic activity and influenced the catalytic activity at low reaction temperatures. This owed to Zr–Ce mixed oxides, which was a key component for NH_3 -SCR catalysts because of their favorable attributes, such as high temperature phase stability, good redox properties, and acidity [30]. Besides, according to the literature [31], the synergistic interaction between Ce and V species enhanced the reducibility of catalyst and thus improved the catalytic activity. Although the Hg^0 oxidation in SCR atmosphere was unsatisfactory, it is still encouraging because lower space velocity and the typical flue gas with HCl would result in higher Hg^0 oxidation efficiency.

3.1.2. Effect of Hg^0 on NO conversion

The main objective of this work was to achieve simultaneous removal of Hg^0 and NO using V/ZrCe catalysts. In real applications, gas-phase mercury is the typical components of flue gas. Thus, the effect of Hg^0 on NO conversion efficiency was studied. Based on the results in Fig. 3, NO conversion efficiency at different Hg^0 concentration exhibited similar trends. It was obvious that NO conversion efficiency increased with the increase of reaction temperature from 100 to 250 °C and then decreased slightly from 300 to 400 °C. Besides, NO conversion efficiency at different Hg^0 concentration was nearly the same to each other, which indicated that the addition of Hg^0 had little impact on NO conversion. It might be because the Hg^0 concentration (less than $140 \mu\text{g}/\text{m}^3$) was extremely small compared to NO concentration (700 ppm).

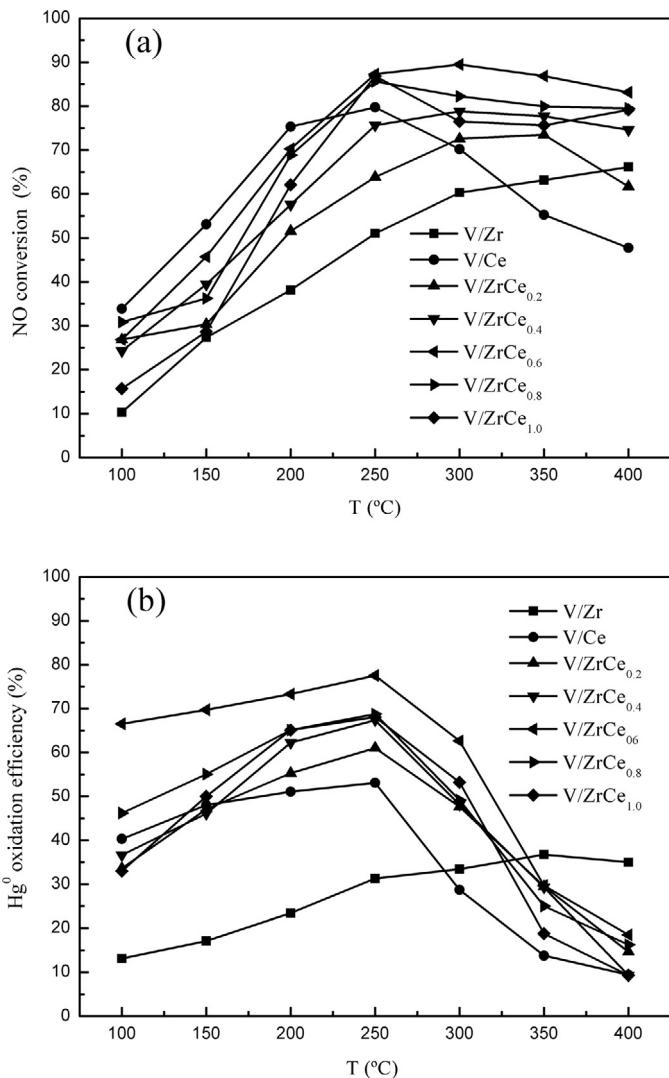

Fig. 2. Simultaneous removal of Hg^0 and NO on various catalysts in SCR atmosphere ($\text{NH}_3/\text{NO} = 1$). (Reaction condition: $70.0 \mu\text{g}/\text{m}^3 \text{Hg}^0$, 700 ppm NO , $\text{NH}_3/\text{NO}: 1, 6\% \text{O}_2$, 250 mg of sample, total flow rate $500 \text{ mL}/\text{min}$, GHSV $100,000 \text{ h}^{-1}$).

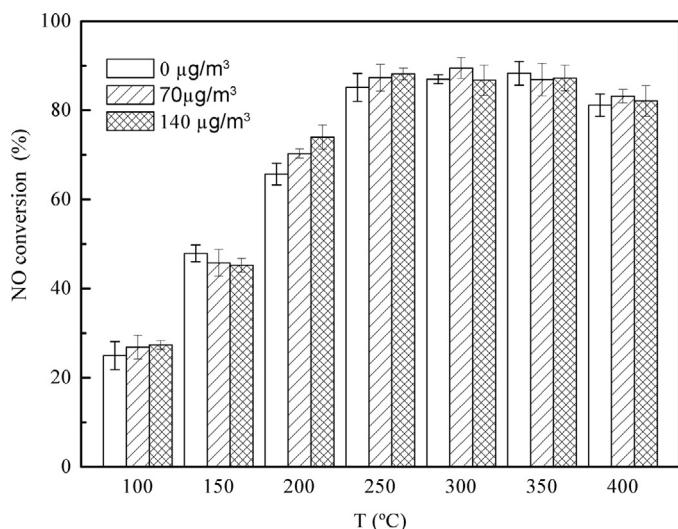

Fig. 3. Effects of Hg^0 on NO conversion efficiency. (Reaction condition: $0 \sim 140.0 \mu\text{g}/\text{m}^3 \text{Hg}^0$, 700 ppm NO , $\text{NH}_3/\text{NO}: 1, 6\% \text{O}_2$, 250 mg of sample, total flow rate $500 \text{ mL}/\text{min}$, GHSV $100,000 \text{ h}^{-1}$).

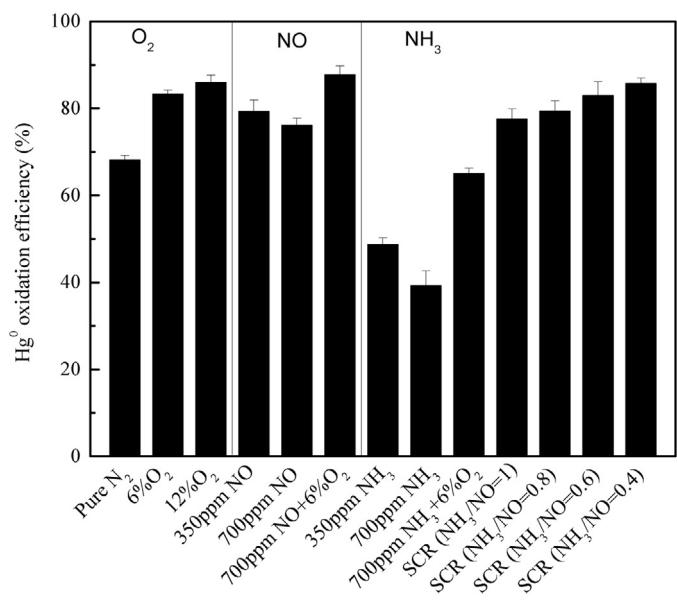

Fig. 4. Effects of SCR gas components on Hg^0 oxidation over $\text{V/ZrCe}_{0.6}$ catalysts at 250°C . (Reaction condition: $70.0 \mu\text{g}/\text{m}^3 \text{Hg}^0$, $0\% \sim 12\% \text{O}_2$; $0 \sim 700 \text{ ppm NH}_3$, $\text{NH}_3/\text{NO}: 0.4 \sim 1$, 250 mg of sample, $500 \text{ mL}/\text{min}$ total flow rate and GHSV $100,000 \text{ h}^{-1}$).

3.1.3. Effect of SCR gas components on Hg^0 oxidation

3.1.3.1. Effect of O_2 . Effects of SCR gas components on Hg^0 oxidation over the $\text{V/ZrCe}_{0.6}$ catalyst are summarized in Fig. 4. O_2 is critical for the oxidation of Hg^0 . Hg^0 oxidation was observed to be 83.2% at 6% O_2 , which was higher than the Hg^0 oxidation of 68.1% under pure N_2 gas flow. The loss of Hg^0 on the $\text{V/ZrCe}_{0.6}$ catalyst in pure N_2 atmosphere was due to the reaction between Hg^0 and the surface oxygen which could act as oxidants to sustain HgO formation on the surface of sample [32]. Based on the H_2 -TPR and XPS results discussed later, the oxygen on the surface of the catalyst not only supplied abundant chemisorbed and lattice oxygen, but also enhanced the oxidation of NH_3 and the formation of highly reactive surface nitrates. Therefore, when 6% O_2 was introduced, gas-phase O_2 regenerated the lattice oxygen and replenished the chemisorbed oxygen, which facilitated Hg^0 oxidation. However, when O_2 concentration further increased to 12%, no obvious increase of Hg^0 oxidation was detected. This result suggested that 6% O_2 was sufficient for Hg^0 oxidation.

3.1.3.2. Effect of NO. The Hg^0 oxidation of the $\text{V/ZrCe}_{0.6}$ catalyst increased from 68.1% to 79.3% with the addition of 350 ppm NO. It indicated that the activity of $\text{V/ZrCe}_{0.6}$ catalyst for Hg^0 oxidation was enhanced with the presence of NO. This was probably because a fraction of NO reacted with the surface oxygen of catalyst to form NO_x species which can cause Hg^0 oxidation [33]. Besides, a Hg^0 oxidation of 76.1% was observed when NO concentration further increased to 700 ppm, which was still higher than that observed in pure N_2 atmosphere. However, 350 ppm and 700 ppm NO balanced in N_2 was lower than that observed under 6% O_2 atmosphere. It was hypothesized that part of the NO reaction consumed the surface oxygen which resulted in a slight decrease of Hg^0 oxidation. Hence, once 6% O_2 was added, gas-phase O_2 replenished the surface oxygen, which was sufficient for NO conversion and Hg^0 oxidation. Therefore, the coexistence of NO and O_2 would be beneficial for the Hg^0 oxidation.

3.1.3.3. Effect of NH_3 . In this study, NH_3 is as a reducing agent in the SCR reaction. The V/Ce catalysts, which are developed for simultaneous removal of NO and Hg^0 , would probably be used under SCR

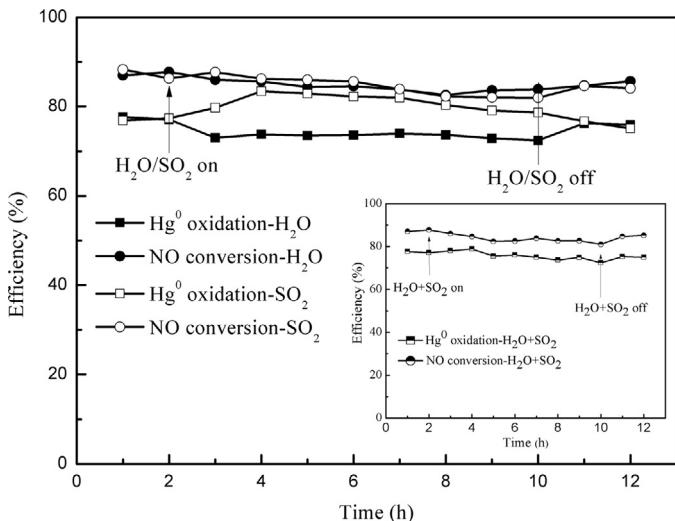

Fig. 5. The effect of H₂O and SO₂ on simultaneous removal of Hg⁰ and NO over V/ZrCe_{0.6} catalysts at 250 °C. (Reaction condition: 70.00 μg/m³ Hg⁰, 700 ppm NO, NH₃/NO: 1, 6% O₂, 300 ppm SO₂ (when used), 8 vol.% H₂O (when used), 250 mg of sample, 500 mL/min total flow rate and GHSV 100,000 h⁻¹).

conditions where NH₃ is present. Therefore, it is necessary to study the effect of NH₃ on Hg⁰ oxidation. 350 or 700 ppm of NH₃ was added into pure N₂ exhibited a significant inhibitive effect on Hg⁰ oxidation. However, the Hg⁰ oxidation efficiency increased from 39.3% to 65.0% when 6% O₂ was introduced into the gas flow containing 700 ppm NH₃. Some researchers [34,35] believe that the adsorbed NH₃ most probably reacted with the surface oxygen to form NH₂ and OH. The reaction process is as follows:

where O* is active surface oxygen of catalyst. The consumption of surface oxygen by NH₃ was mostly responsible for the decrease of Hg⁰ oxidation. The presence of gas-phase O₂ could offsets the greater part of the inhibitive effect of NH₃ because the consumption of surface oxygen can be replenished. Besides, the effect of NH₃/NO ratio on Hg⁰ oxidation was also investigated. The Hg⁰ oxidation efficiency increased from 77.6% to 85.7% with the decrease of NH₃/NO ratio from 1.0 to 0.4. It would be deduced that the SCR reaction consumed NH₃, which could offsets a part of the inhibitive effect of NH₃ on Hg⁰ oxidation. Furthermore, the surplus NO should facilitate Hg⁰ oxidation when the NH₃/NO ratio was smaller than 1.0 [36]. In general, Hg⁰ oxidation was inhibited in SCR atmosphere owing to the presence of NH₃. Nevertheless, it is still an inspiring Hg⁰ oxidation in typical flue gas with HCl.

3.1.4. Effect of H₂O and SO₂ on simultaneous removal of NO and Hg⁰

Because the combustion exhaust contains water vapor and SO₂ in practical applications, the influence of H₂O/SO₂ on the activity over V/ZrCe_{0.6} catalyst was investigated. As shown in Fig. 5, the addition of 8 vol.% H₂O had a negligible inhibition effect on NO conversion and Hg⁰ oxidation. The Hg⁰ oxidation and NO conversion remained above 72.9% and 82.6% respectively for the entire 8 h, suggesting that V/ZrCe_{0.6} catalyst exhibited strong resistance to H₂O poisoning at 250 °C. The effect of 300 ppm SO₂ over V/ZrCe_{0.6} catalysts activity is also shown in Fig. 5. The NO conversion showed a slight decline over time and decreased to 82.0% when SO₂ was introduced into the reaction atmosphere. After removing SO₂, the NO conversion was partially restored. This result indicated that SO₂ inhibited the catalytic activity slightly at 250 °C, which may be

attributed to the deposition of ammonium sulfate/bisulfate on the surface. It is interesting to note that Hg⁰ oxidation efficiency was first increased and then slightly decreased over time in the presence of SO₂. This indicated that promotional effect of SO₂ on Hg⁰ oxidation was obtained. It was very likely that SO₂ reacted with the surface oxygen to form SO₃ that were responsible for the enhanced Hg⁰ oxidation [37]. A promotional effect of SO₂ on Hg⁰ oxidation is presented as follow:

Fig. 5 (inset) shows the influence of H₂O and SO₂ on the catalytic performance of catalyst. When 8 vol.% H₂O and 300 ppm SO₂ were added into the SCR atmosphere (NH₃/NO = 1), a slight decline of the NO conversion was observed over time. The Hg⁰ oxidation did not show any decrease for the first 2 h. However, further increasing the reaction time resulted in a slight decline of Hg⁰ oxidation and decreased to 72.4%. It might be because H₂SO₄ can form when SO₂, O₂, and H₂O co-exist, which will likely affect the behavior of Hg⁰ on the surface of catalyst [37]. Then the H₂SO₄ reacted with HgO to form HgSO₄. After the removal of SO₂ and H₂O, the catalytic activity recovered but not returned to the original level yet. It implied that the ammonium sulfate/bisulfate which blocked the active sites led to a slight decrease of catalytic activity. However, the catalytic activity was still maintained at a relatively high level during the measured period. Combined with the result of upper experiment, the V/ZrCe_{0.6} catalyst has excellent H₂O and SO₂ durability, which is very competitive for practical application on simultaneous removal of NO and Hg⁰.

3.2. Structural properties

3.2.1. BET

The BET specific surface area, pore volume and pore size of the catalysts are shown in Table 1. The BET surface area of V/ZrCe_x was larger than that of V/Zr and V/Ce. Besides, with increasing the molar ratio of Ce/Zr, a marked increase in the BET surface area was observed. In particular, V/ZrCe_{0.6} catalyst displayed the largest surface area, which was in consistent with the best catalytic performance. The material owning higher BET specific surface area could provide more surface active sites for the reactants [38,39], by which the catalytic activity could be promoted. Besides, it was concluded that some synergistic effect must exist between the Ce and Zr oxide species. The V/ZrCe_x catalysts with higher surface area may be attributed to a transformation of the bulk, regular crystals to an amorphous or crystallite structure during co-precipitation, as shown by XRD. Meanwhile, the amorphous or crystallite structure usually has a higher surface area than the crystallized structure [40].

3.2.2. XRD and SEM

Fig. 6 shows the XRD patterns and the SEM images of the prepared samples. To identify the crystal structures of catalysts, XRD was characterized. As shown in Fig. 6(a), the main peaks of V/Ce in the diffraction profiles can be attributed to CeO₂ with the cubic fluorite structure (PDF-ICDD 43-1002) [4]. The diffraction peaks of the V/Zr showed monoclinic ZrO₂ (PDF-ICDD 36-0420) [41]. For the V/ZrCe_x catalysts, the diffraction peaks were obviously attributed to the cubic fluorite structure of CeZrO₄ (PDF-ICDD 54-0017), indicating that the CeO₂-ZrO₂ solid solution was formed [42]. Interestingly, no XRD lines corresponding to crystalline vanadia were noted. It can be assumed that the impregnated vanadium oxide was in a highly dispersed or amorphous state on the surface of the support. Besides, full width at half maximum (FWHM)

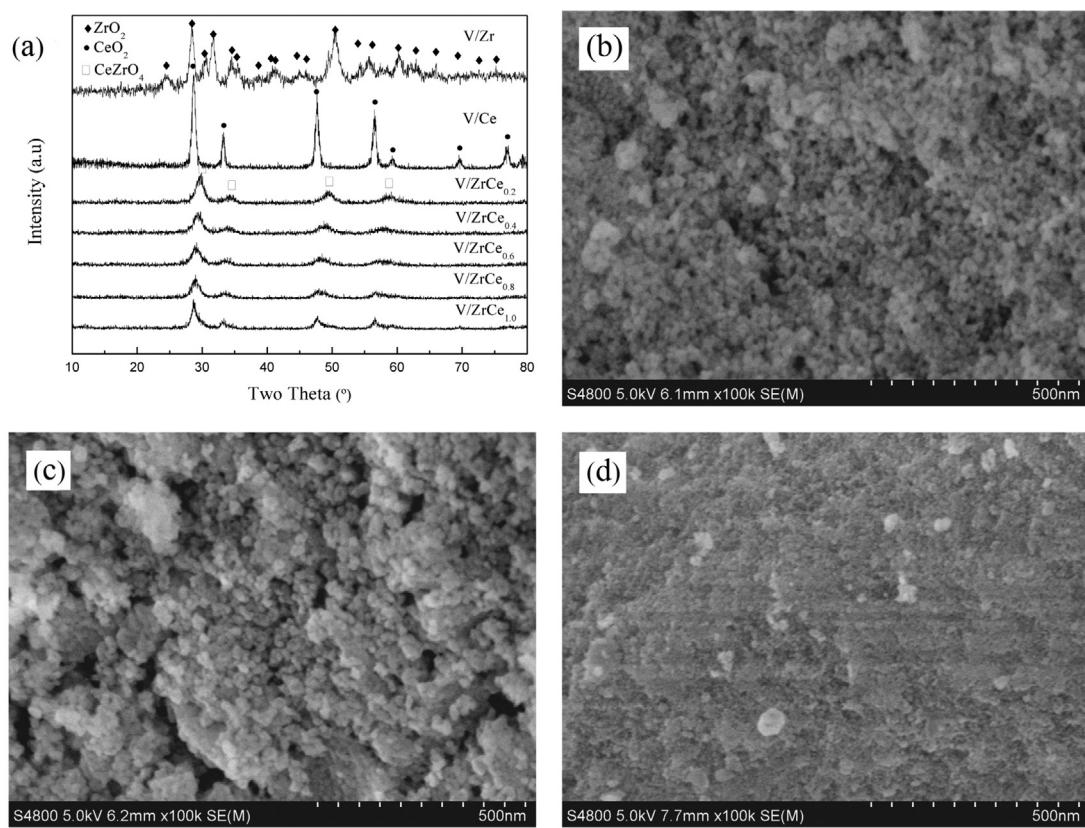

Fig. 6. (a) XRD patterns of various catalysts; SEM photographs of (b) V/Ce, (c) V/Zr, (d) V/ZrCe_{0.6}.

enlarges and the peak intensity decreased on V/ZrCe_x catalysts. This indicated that the formation of CeO₂–ZrO₂ solid solution affected the structure of the catalyst, and it weakened the crystallinity and reduced the crystalline size. It was reported that amorphous or crystallite materials with enormous structure distortion would provide more active sites for catalytic reactions than crystalline materials, which was probably responsible for the high catalytic activity [43]. These results also indicated that the ZrCe_x support was beneficial for the dispersion of active components and resulted in high NO conversion and Hg⁰ oxidation.

SEM studies were conducted to investigate the surface morphology of the catalysts. As displayed in Fig. 6(b)–(d), the nanoparticles of the V/Ce evenly dispersed without agglomeration, whereas the agglomeration was observed over the V/Zr catalyst. The particle size of V/ZrCe_{0.6} catalysts observed with SEM was smaller than that of V/Zr and V/Ce, which could be due to the interaction between Ce and Zr during preparation process of V/ZrCe_{0.6} catalyst. The SEM image of V/ZrCe_{0.6} catalysts at high magnification showed homogeneous distribution of nanoparticles with an average size of around 5–25 nm. Such results indicated that Ce can prevent the aggregation of Zr particles. Combined with the BET and XRD results, it could be inferred that the combination of Ce and Zr significantly affected texture properties of catalysts, which played an important role in catalytic activity.

3.2.3. NH₃-TPD

The NH₃-TPD curves for various catalysts are shown in Fig. 7. After deconvoluting, three main ammonia desorption peaks were observed over the entire desorption temperature range. A small peak was located at 159.4–191.2 °C, and two large ammonia desorption peaks were located at 225.6–250.7 °C and 295.7–340.7 °C, respectively. According to the literatures [23,38,44,45], the peak at 159.4–191.2 °C should be assigned to NH₃ desorbed by the weak

acid sites; the peak at 225.6–250.7 °C was ascribed to the desorption of coordinated NH₃ bound to Brønsted acid sites; the peak at 295.7–340.7 °C was ascribed to the desorption of coordinated NH₃ bound to the Lewis acid sites. Compared with the V/Zr catalysts, the addition of Ce caused broadening of desorption peak. Besides, V/ZrCe_{0.2} had the smallest desorption peak, the intensity of desorption peak enhanced with the Ce/Zr ratio varying from 0.2 to 0.6. However, the intensity declined with further increasing Ce/Zr ratio. V/ZrCe_{0.6} had the biggest desorption peak area, denoting that it had the most acid amount. Combined with the BET results, the biggest desorption peak area of V/ZrCe_{0.6} may be caused by the biggest surface area.

3.3. Redox properties

3.3.1. H₂-TPR

As illustrated in Fig. 8, H₂-TPR analysis was conducted to study the redox property of V/Zr, V/Ce and V/ZrCe_{0.6} catalysts. Some researchers reported that pure ZrO₂ does not show any reduction peak below 900 °C [42,46]. Therefore, V/Zr catalysts showed a major broad peak with maximum at 456 °C, which can be likely corresponded to the reduction of V⁵⁺ to V³⁺ [22]. V/Ce exhibited the reduction peaks at around 550 °C, which was assigned to the reduction of surface oxygen [4]. And the noticeable and broad shoulder peak at 716 °C was ascribed to the reduction of lattice oxygen [4]. The peaks of V/ZrCe_{0.6} at 580 °C were assigned to the reduction of ceria-zirconia mixed oxides [47,48]. Meanwhile, it can be seen that the peak area of V/ZrCe_{0.6} was larger than that of V/Zr and V/Ce catalyst, which indicated that redox ability of V/ZrCe_{0.6} was greatly improved. Higher redox ability of V/ZrCe_{0.6} could enhance the mobility of surface oxygen due to the strong synergistic effect among Zr, Ce and V species. It was believed that the synergistic effect led to severe structural distortion and affluent oxygen defects

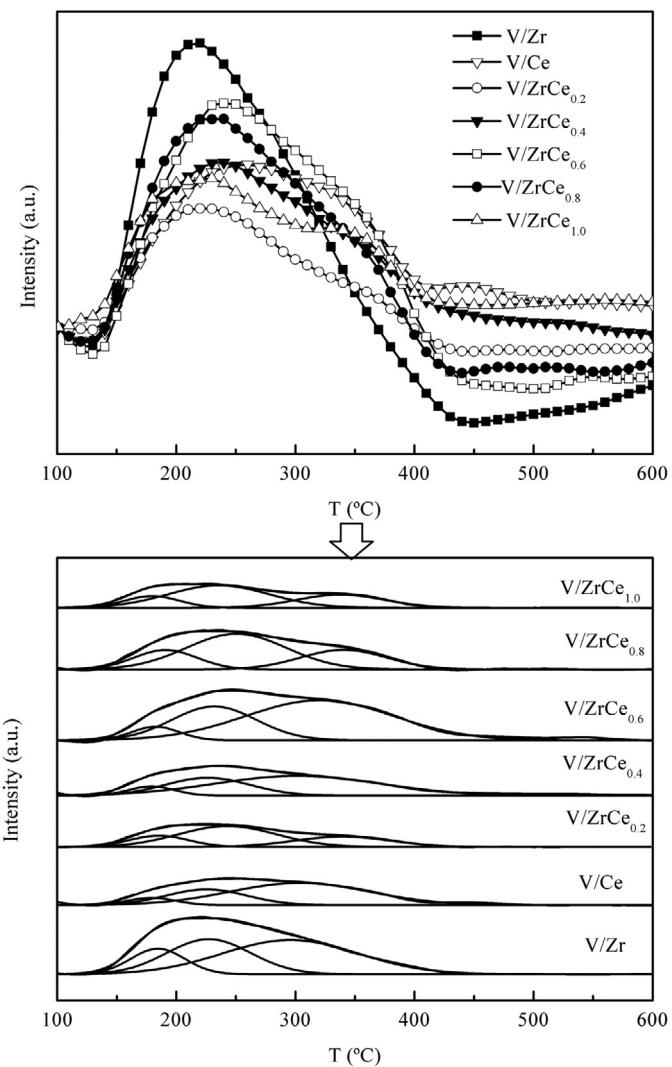

Fig. 7. NH₃-TPD profiles of V/ZrCe catalysts.

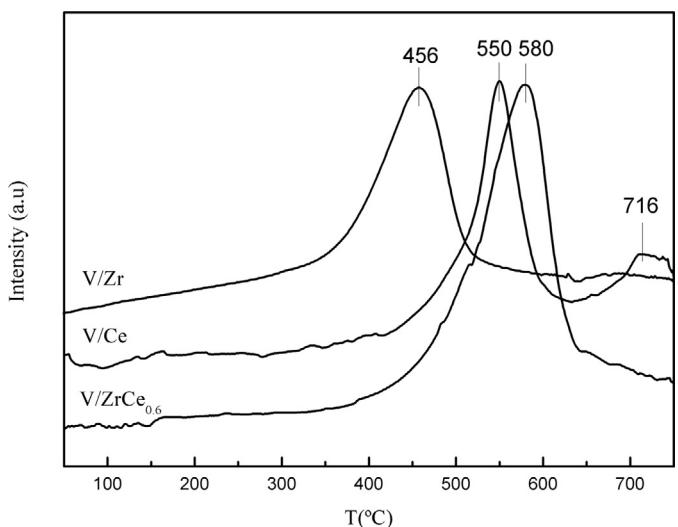

Fig. 8. H₂-TPR profiles of various catalysts.

[49,50]. Combined with the results of XPS, the good reducibility owing to the increase of the amount and the kinds of reactive oxygen species, can provide a facile redox process that would contribute to enhancing the catalytic activity [51].

3.3.2. XPS

XPS measurements were carried out over the fresh and used V/ZrCe_{0.6} catalyst to provide information about the surface interaction and the chemical state of elements on the surface of catalysts. The used V/ZrCe_{0.6} catalyst was carried out on the fixed bed reaction system under SCR atmosphere with or without SO₂ at 250 °C. As shown in Fig. 9(a), the O 1s peak was fitted into two sub-bands: the peak at around 529.2–530.3 eV was attributed to the lattice oxygen O²⁻ (denoted as (Oβ)), while the one at around 531.3–532.3 eV corresponded to the chemisorbed oxygen (denoted as (Oα)) such as O₂²⁻ or O⁻ [52]. However, O 1s of V/Ce and V/Zr shifted to the low binding energy direction. Besides, the binding energy (BE) value of the V/Ce catalyst was lower than those of the V/Zr and V/ZrCe_{0.6} catalysts, showing that Ce donated more electrons to oxygen species. The BE of Oβ peaks tended to shift towards higher BE (approximately 1.0 eV) over V/ZrCe_{0.6} catalysts, which was related to the partial conversion of Ce⁴⁺ into Ce³⁺ species [53]. The ratio of Oβ, calculated by Oβ/(Oα + Oβ), over V/ZrCe_{0.6} (36.9%) was higher than that over V/Ce (30.6%) and V/Zr (24.0%), demonstrating that the amount of lattice oxygen species on V/ZrCe_{0.6} catalysts was increased. Oxygen species can be stored/released by ceria via the redox shift between Ce⁴⁺/Ce³⁺ [54], leading to the increase of surface mobile oxygen, which was beneficial to the redox properties.

Fig. 9(b) depicts the XPS spectra in the V 2p region for the V/ZrCe_{0.6} catalysts. Two peaks at 518.0 and 519.8 eV for the fresh V/ZrCe_{0.6} catalysts corresponded to the oxidation states V⁴⁺ and V⁵⁺, respectively [55]. Binding energy of V⁵⁺ on catalyst surface increased after the reaction without SO₂, while binding energy of V⁴⁺ slightly decreased, suggesting that some V⁵⁺ was reduced to V⁴⁺ [56]. Furthermore, the V⁵⁺/V⁴⁺ ratio decreased from 1.2 to 1.0, which also indicated that V⁴⁺ species increased after reaction without SO₂. According to the previous studies [16], Hg⁰ in flue gas can react with V₂O₅ on catalyst surface and then form V⁴⁺ species and HgO. That was the reason why V⁴⁺ content increased. It's worth noting that the catalysts were found to be reported for V³⁺ (514.5 eV), V⁴⁺ (516.4 eV) and V⁵⁺ (518.3 eV) after the reaction with SO₂. Dunn et al. [57] proposed that SO₂ oxidation to SO₃ occurs on V₂O₅, and at the same time the valence of V⁵⁺ ions changes to V³⁺. However, the content of V⁵⁺ has remained fairly constant compared to the fresh catalyst. The catalyst would maintain excellent catalytic performance for relative long time. This could be because V⁵⁺ were re-oxidized by oxygen molecules (O_{2(g)}) or adsorbed oxygen species on the surface (O_{ad}) [58]. In addition, we found that the conversion of SO₂ to SO₃ over V/ZrCe catalyst was less than 1% during the experiment, which was negligible. SO₃ could react with Hg⁰ to produce HgSO₄. The reactions could be described as:

The XPS results of Ce 3d for V/ZrCe_{0.6} are shown in Fig. 9(c). The bands labeled u, u'', u''', v, v'' and v''' are assigned to Ce⁴⁺, whereas the peaks labeled u' and v' are ascribed to Ce³⁺ ions. It was evident that the coexistence of Ce⁴⁺ and Ce³⁺ over the fresh V/ZrCe_{0.6} catalysts offered the possibility of oxygen storage and release, which enhanced the catalyst activity. Based on the peak areas, Ce⁴⁺ oxide was the primary form, which was considered to be beneficial for the oxidation reactions [59]. The presence of Ce³⁺ could create charge imbalance, the vacancies and unsaturated chemical bonds on the catalyst surface, leading to more surface oxygen species formed

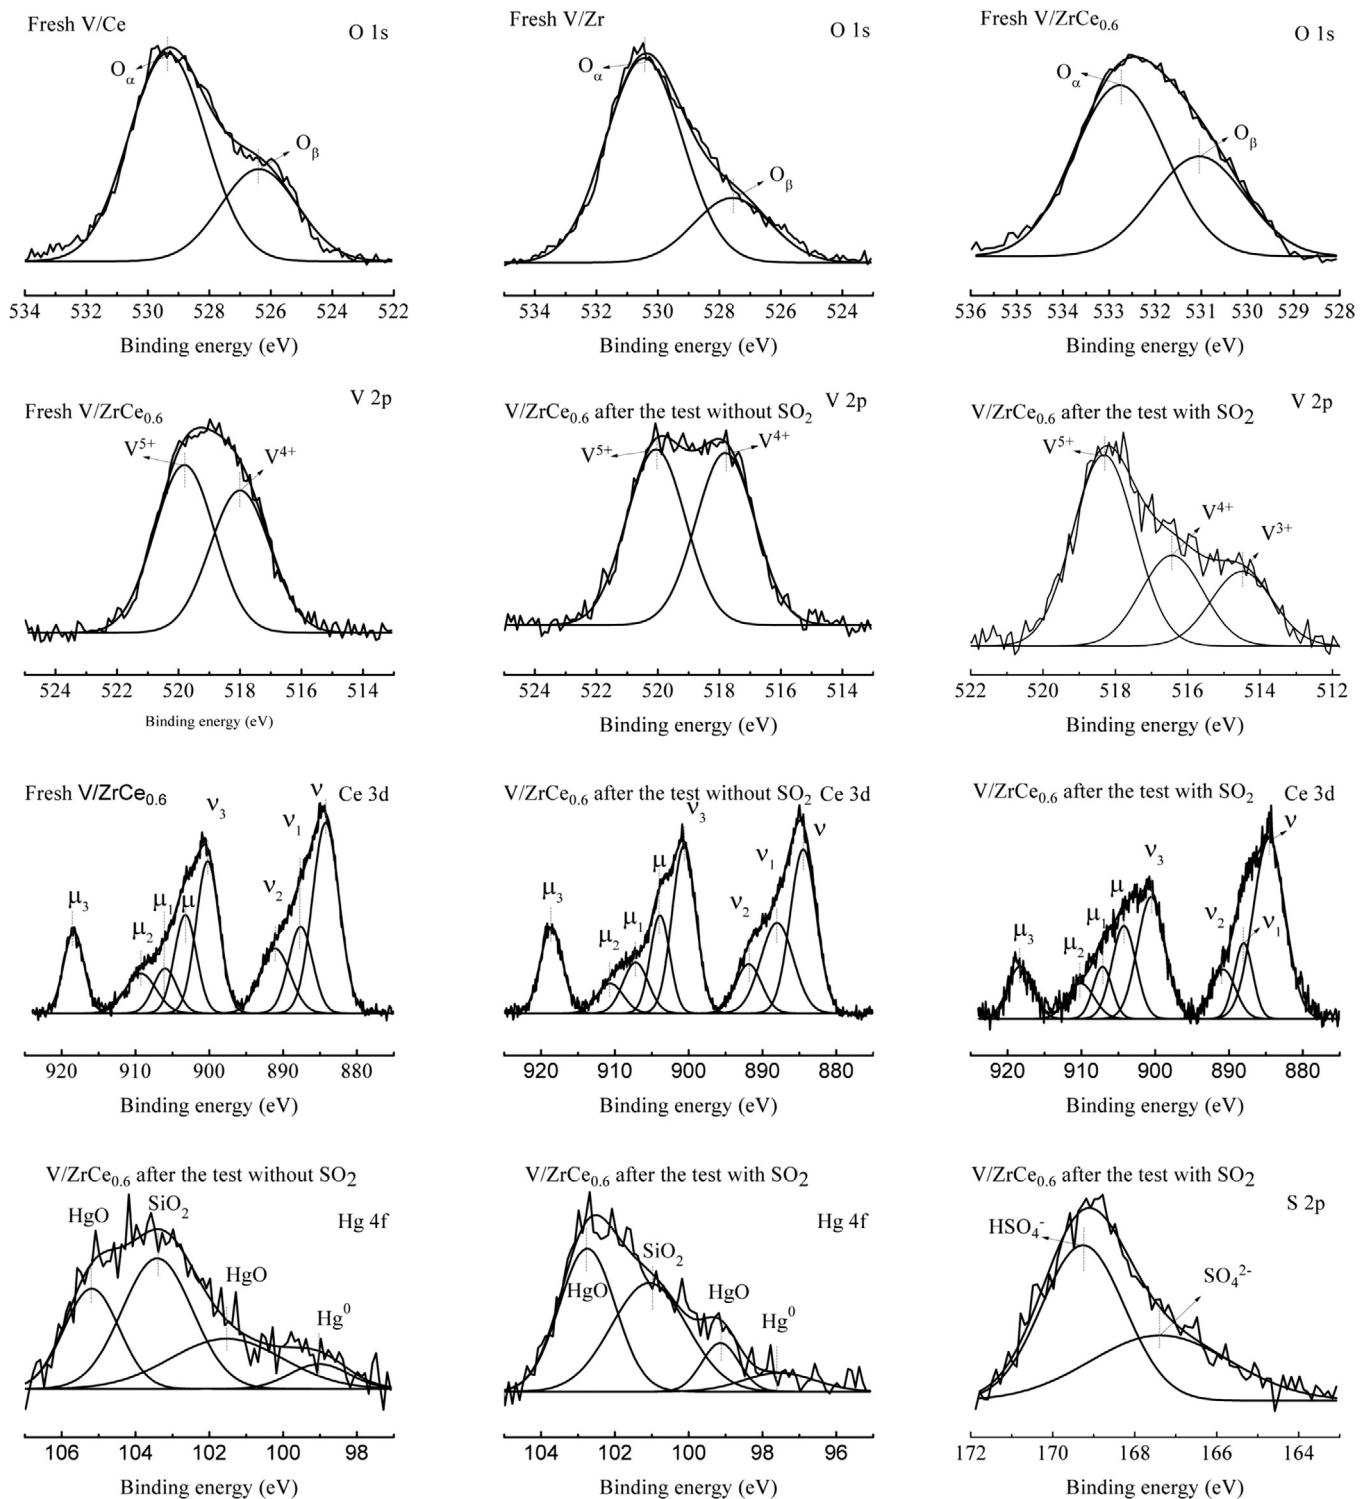

Fig. 9. XPS spectra of the catalysts over the spectral regions of Ce 3d, V 2p and O 1s before the test, and Ce 3d, V 2p, Hg 4f, and S 2p after the test with or without SO₂ (Reaction condition: 70.00 µg/m³ Hg⁰, 700 ppm NO, NH₃/NO: 1, 6% O₂, 0/300 ppm SO₂, 250 mg of sample, 500 mL/min total flow rate and GHSV 100,000 h⁻¹).

[60]. Combined with results of XRD, XRD patterns did not exhibit extra peaks, indicating no phase segregation occurred. Liu et al. [61] found that the enhancement of homogeneous Ce and Zr atoms could ease the valence change of Ce (Ce⁴⁺ → Ce³⁺). After the reaction without SO₂, the ratio of Ce⁴⁺/Ce³⁺ decreased from 5.0 to 3.3 compared to the fresh catalyst, indicating that some Ce⁴⁺ was reduced to Ce³⁺ during the reaction. The generation of V⁴⁺ together with Ce³⁺ is indicative of the redox equilibrium (Ce³⁺ + V⁵⁺ ⇌ Ce⁴⁺ + V⁴⁺).

The redox couple Ce⁴⁺/Ce³⁺ could transfer electrons to V⁵⁺, which was the enhancement of reduced vanadium species. The ratio of Ce⁴⁺/Ce³⁺ increased to 6.1 after the reaction with SO₂, which may be due to the oxidation of Ce³⁺ by O₂ in the presence of SO₂.

Hg⁰ oxidation by V/ZrCe_{0.6} catalysts may be attributed to the Mars-Maessen mechanism [62,63]. The Hg 4f XPS patterns are shown in Fig. 9(d). The characteristic peak at 99.0 eV was ascribed to Hg⁰ [64]. The peak at 101.3 and 105.2 eV corresponded to Hg 4f

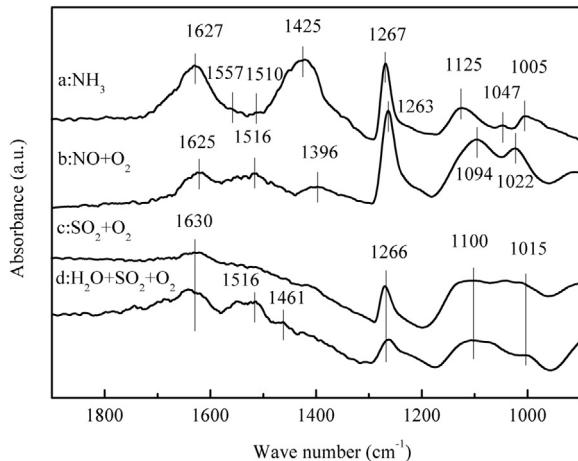

Fig. 10. FT-IR spectra taken upon V/ZrCe_{0.6} catalysts.

7/2 and Hg 4f 5/2, respectively, and were assigned to HgO [65,66]. The peak at 103.4 eV was attributed to Si 2p of SiO₂ in quartz wool [65]. This indicated that the main species of mercury was HgO on the surface of V/ZrCe_{0.6} after the test without SO₂. The adsorption of Hg⁰ occurred on the surfaces of V/ZrCe_{0.6} catalysts followed by a subsequent heterogeneous oxidative transformation of Hg⁰ to HgO by reactive surface oxidants [62]. At the same time, the Hg 4f peaks of V/ZrCe_{0.6} after the test with SO₂ shifted to the low binding energy direction, which centered at about 99.1 and 102.8 eV. Combined with the XPS results in the S 2p region, the results were further confirmed that the oxidized mercury may transform to HgSO₄ in the presence of SO₂. The S 2p peaks mainly centered at 167.4 and 169.3 eV, which may be ascribed to SO₄²⁻ and HSO₄⁻, respectively [67]. During the reaction, the formation of SO₄²⁻ was also supported by the spectra of V 2p region.

3.4. FT-IR characterization: study of NH₃ and NO_x adsorption abilities and influence of H₂O and SO₂

The FT-IR spectra of V/ZrCe_{0.6} catalyst at different gases for 60 min are showed in Fig. 10. As shown in Fig. 10a, several bands attributed to different form of NH₃ molecule were observed on the catalyst surface. The bands at 1005 cm⁻¹, 1047 cm⁻¹, 1125 cm⁻¹, 1267 cm⁻¹ and 1627 cm⁻¹ can be attributed to asymmetric and symmetric bending vibrations of NH₃ coordinated on Lewis acid sites [34,68], while the band at 1425 cm⁻¹ can be assigned to asymmetric and symmetric bending vibrations of NH₄⁺ species on Brønsted acid sites [25,69,70]. The band at 1510 cm⁻¹ and 1557 cm⁻¹ were assigned to amide species (-NH₂) [68]. This indicated that the V₂O₅ had an ability to oxidize (or dehydrogenize) NH₃ into NH₂, which was considered as the intermediate of the SCR reaction [71,72]. Fig. 10b shows the FT-IR spectra results of NO_x adsorption over V/ZrCe_{0.6} catalysts. After NO + O₂ adsorption, several weak bands were detected at 1022, 1094, 1263, 1396, 1516 and 1625 cm⁻¹. The bands at 1022 and 1094 cm⁻¹ were attributed to anionic nitrosyl NO⁻ species, which can be oxidized to nitrate or nitrite species in the presence of oxygen [73]. The bands at 1263 and 1625 cm⁻¹ were ascribed to bridging nitrate [74], while the band at 1396 cm⁻¹ can be attributed to M-NO₂ nitro compounds [75]. Besides, a series of successive peaks in the range of 1500–1580 cm⁻¹ could be assigned to NO₂-containing species, like nitrito (O-bound NO₂) and nitratato (NO₃) species [76]. Some researchers [77,78] demonstrated that the adsorbed nitrates species could participate in the redox reaction sufficiently. At the same time, the FT-IR spectra of SO₂ and H₂O adsorption were also conducted. As shown in Fig. 10c, several bands at 1630, 1266,

1100, and 1015 cm⁻¹ were detected on the catalyst. The band at 1630 cm⁻¹ was assigned to δ_{HOH} of H₂O, suggesting that surface water was formed [79]. Three absorption bands between 1000 and 1300 cm⁻¹ were also discernible on the catalysts, suggesting that the bidentate sulfates formed [80,81]. Chang et al. [81,82] held the opinion that the bidentate sulfate could provide new acid sites for NH₃ adsorption and the emerging sites were mainly Lewis acid sites. Moreover, the formation of bidentate sulfate would greatly increase the amount of NH₄⁺ [83]. These would alleviate the inhibition of ammonium sulfate/bisulfate deposition on the catalyst. It is noteworthy that similar bands also appeared after H₂O + SO₂ + O₂ treatment. The major difference was that two new absorption bands at 1516 and 1461 cm⁻¹ appeared when SO₂, O₂, and H₂O co-exist. These bands were attributed to the vibrations of the surface hydroxyl species (OH), demonstrating that gaseous H₂O and O₂ were prone to forming active oxygen and hydroxyl on the surface [80].

3.5. Mechanism discussion

From the above studies, the reaction over the surface of V/ZrCe_{0.6} catalysts included both Hg⁰ oxidation and NO conversion. The cerium can occupy two oxidation states [CeO₂ (Ce⁴⁺) ⇌ Ce₂O₃ (Ce³⁺)], allowing ceria from the CeO₂-ZrO₂ support to accommodate more surface lattice oxygen species. The existence of redox equilibrium (Ce³⁺ + V⁵⁺ ⇌ Ce⁴⁺ + V⁴⁺) could be beneficial to the NH₃-SCR reaction and Hg⁰ oxidation. On one hand, combining the results obtained in this study and the literature [84], Hg⁰ oxidation mainly occurs via a Mars-Maessen mechanism. Hg⁰ (g) firstly absorbed on the surface of the catalysts to form Hg(ad), then V₂O₅ and CeO₂ offered the lattice oxygen for the oxidation of Hg(ad). The reduced V₂O₄ and Ce₂O₃ can be converted back to their original state by O₂ in the gas. The redox equilibrium enhanced the reducibility of vanadia species. In addition, SO₂ participated in the Hg⁰ oxidation reaction and HgSO₄ was generated. NO could be oxidized into NO₂ by surface oxygen, and NO₂ could react with Hg⁰ to form Hg(NO₃)₂. The oxidation mechanism of Hg⁰ can be described as follows:

On the other hand, Both Lewis and Brønsted acid sites exist on the surface of V/ZrCe_{0.6} catalysts, leading to the appearance of coordinated NH₃, NH₄⁺, -NH₂ and other intermediates from NH₃ oxidation. NO can be oxidized to NO₂ and intermediate nitrate on the catalyst surface in the presence of oxygen. The adsorbed NH₃ or NH₄⁺ would react with the NO₂ species generated at the surface to form intermediate species, which further react with gaseous NO or adsorbed NO to form N₂. Furthermore, -NH₂ could react with NO to form N₂. Based on the XPS and FT-IR spectroscopic results as well as the earlier reports [68,85], the possible mechanism for the SCR reaction of NO with NH₃ can be facilitated as follows:

4. Conclusions

A series of V/ZrCe_x catalyst was prepared by a co-precipitation method for simultaneous removal of NO and Hg⁰. V/ZrCe_{0.6} exhibited superior NO conversion (87.3%) and Hg⁰ oxidation efficiency (77.6%) in SCR atmosphere (NH₃/NO=1) at 250 °C. The catalyst also exhibited a better SO₂ and H₂O durability due to the formed of bidentate sulfates. The addition of Hg⁰ had little impact on NO conversion because of the smaller Hg⁰ concentration. NH₃ consumed the surface oxygen, hence inhibiting Hg⁰ oxidation. However, gas-phase O₂ regenerated the lattice oxygen and replenished the chemisorbed oxygen, which facilitated Hg⁰ oxidation. NO and SO₂ had a promoting effect on Hg⁰ oxidation in the presence of O₂. In addition, the characterization results showed that the features of V/ZrCe_{0.6}, such as lower crystallinity, better texture properties, strong redox ability and high reactive nitrate together with NH₃ species, were favorable for the superior catalytic performance. The redox equilibrium (Ce³⁺ + V⁵⁺ ↔ Ce⁴⁺ + V⁴⁺) was beneficial to the Hg⁰ oxidation and NO conversion. Based on the results, the catalytic mechanism for simultaneous removal of Hg⁰ and NO over V₂O₅/ZrO₂-CeO₂ was proposed: 2NH₃/NH₄⁺(ad) + NO₂(ad) + NO(g) → 2N₂ + 3H₂O + 2H⁺, Hg(ad) + O^β → HgO(ad).
